ABSTRACT

Posterior capsule opacification (PCO) remains the most common complication following cataract surgery, and transforming growth factor-beta 2 (TGF-β2) is a key mediator of its pathogenesis. This systematic review evaluates the culture media, TGF-β2 concentrations, and incubation periods used in *in vitro* PCO models to identify conditions that favour reproducibility. A comprehensive literature search was performed in PubMed, ScienceDirect, SpringerLink, Taylor & Francis and SAGE Journals using the MeSH terms “posterior capsule opacification” OR “posterior capsular opacification” OR “capsule opacifications” OR “secondary cataract” OR “PCO” AND “lens epithelial cells” AND “TGF-β2” OR “epithelial–mesenchymal transition (EMT)”. Original full-text English articles published between 1 June 2014 and 30 July 2024 were included; abstracts, preprints, and non-English reports were excluded. Sixteen eligible studies were retrieved. Three studies employed 5 ng/mL TGF-β2, whereas seven used 10 ng/mL; both doses induced morphological changes in lens epithelial cells. Nine studies utilised Dulbecco’s modified Eagle medium (DMEM). Most experiments (n = 8) incubated cells for 24 h, whereas others extended incubation to ≥ 48 h depending on study design. Collectively, 10 ng/mL TGF-β2, DMEM and an incubation period of 24–48 h represent the most frequently used conditions and may improve the reproducibility of *in vitro* PCO models, ultimately guiding the development of interventions to prevent PCO after cataract surgery.

Key words: Posterior Capsule Opacification, Lens Epithelial Cells, TGF-B2, In Vitro, Time Factors, Culture Media, Systematic Review

INTRODUCTION

Cataracts are the leading cause of blindness worldwide, and surgical extraction remains the standard treatment. Despite technological advances in cataract surgery, posterior capsule opacification (PCO) continues to be a common postoperative complication¹. PCO not only reduces visual acuity but also degrades visual quality, producing symptoms such as halos and diminished contrast sensitivity. It affects approximately 20–40 % of adult and almost 100 % of paediatric cataract patients after surgery, leading to secondary vision loss². PCO develops mainly from the proliferation and migration of residual lens epithelial cells (LECs) stimulated by postoperative inflammation and wound-healing responses. These LECs subsequently undergo transdifferentiation or epithelial–mesenchymal transition (EMT) into fibroblast-like and lens-fiber-like cells, processes driven by growth factors and extracellular-matrix (ECM)-related proteins³. Although PCO is clinically important, there is currently no standardized protocol or standard operating procedure (SOP) for generating *in-vitro* PCO models. This lack of uniformity hampers the

development of preventive measures and research strategies. Establishing standardized model systems would streamline PCO research by minimizing variability in culture media and methodology and by reducing experimental time¹.

Another process initiated during the inflammatory response and wound-healing cascade is the migration of lens epithelial cells (LECs) to the posterior capsule. LECs located at the lens equator can transdifferentiate into cells resembling normal lens fibres, whereas those that remain on the anterior capsule may differentiate into myofibroblasts, thereby promoting posterior capsule opacification (PCO)⁴. A hallmark of PCO formation is the induction of transforming growth factor-beta (TGF-β). During PCO development, TGF-β signals via the SMAD (small mothers against decapentaplegic) cascade in addition to several SMAD-independent pathways. Among the three isoforms, TGF-β2 is the most biologically potent and is the predominant isoform in the eye. TGF-β is present in a latent form within the aqueous humour but is activated after cataract surgery. Activation of TGF-β initiates LEC proliferation, migration and

epithelial-to-mesenchymal transition (EMT)⁵. Prior reviews have examined PCO broadly, encompassing its pathophysiology, surgical techniques, intraocular lens (IOL) designs and pharmacological prophylaxis^{1,4}. Although *in-vitro* models were occasionally discussed, critical technical variables—including culture medium composition, TGF- β 2 concentration and incubation duration—were not systematically analysed. Standardising an *in-vitro* methodology for inducing PCO is essential for progress toward preventive strategies. Effective *in-vitro* models enable a deeper understanding of the cellular mechanisms underlying PCO, allowing investigators to evaluate candidate interventions under controlled conditions. This systematic review therefore synthesises recent evidence to propose optimised parameters for reproducible *in-vitro* PCO models.

MATERIALS AND METHODS

Research Question

This systematic review was conducted in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2020 statement. The research questions were formulated using the Population, Intervention, Comparison, and Outcome (PICO) framework, in which the population corresponded to the investigated cell type; the intervention entailed TGF- β 2 administration; the comparison involved an appropriate control group; and the outcomes of interest were the onset of posterior capsular opacification (PCO), the concentration of TGF- β 2 required to induce PCO, and the composition of the cell-culture medium.

Literature search and eligibility criteria

We included population-based studies that reported the use of TGF- β 2 in posterior capsule opacification (PCO) modeling using lens epithelial cells. Eligibility criteria were predefined and comprised original *in-vitro*, full-text articles published in English between 1 June 2014 and 30 July 2024. Abstracts, preprints, and non-English publications were excluded. Studies employing wounded capsular-bag models or administering additional treatments prior to TGF- β 2 exposure were also excluded, as such models represent a more complex tissue system with intrinsic wound-healing responses that differ from those observed in simplified cell-culture assays. The review protocol was prospectively registered on the Open Science Framework (OSF) (DOI: <https://doi.org/10.17605/OSF.IO/YBXVW>), because PROSPERO does not accept registrations of systematic reviews limited to *in-vitro* studies.

Search strategy and screening

Two investigators (LRW and IK) independently extracted study data from the PubMed, ScienceDirect, SpringerLink, Taylor & Francis, and SAGE Journals databases. A comprehensive search strategy based on Medical Subject Headings (MeSH) terms was implemented in each database as follows: (“posterior capsule opacification” OR “posterior capsular opacification” OR “capsule opacifications” OR “secondary cataract” OR “PCO”) AND (“lens epithelial cells”) AND (“TGF- β 2” OR “epithelial-mesenchymal transition (EMT)”). The search covered the period from 1 June 2014 to 15 July 2024. Three additional researchers (H.S., S.W., and H.K.P.) resolved any discrepancies. The literature search was finalised at the end of September 2024.

Data extraction

Studies were classified according to their respective research methodologies. Two investigators independently extracted data, recording the following variables: title, authors, year of publication, cell type, culture medium, TGF- β 2 dose, PCO timing, procedures employed, and both quantitative and qualitative outcomes.

Data synthesis

The data were synthesized qualitatively. Findings from 16 *in vitro* studies examining TGF- β 2-induced posterior capsular opacification (PCO) changes were summarized to highlight molecular and cellular responses associated with the treatment, specifically whether TGF- β 2 exposure up-regulated epithelial-to-mesenchymal transition (EMT) markers— α -SMA, fibronectin, collagen I, vimentin, and N-cadherin—and/or down-regulated epithelial markers such as E-cadherin and ZO-1. When available, fold-change values were extracted and mapped to a semi-quantitative EMT score according to predefined criteria: mild (+) = 1–2 markers increased <2-fold with minimal morphological change; moderate (++) = 2–3 markers increased 2–4-fold or clear qualitative EMT features; marked (+++) = \geq 3 markers increased \geq 4-fold or consistent EMT evidence across multiple assays. Two reviewers (I.K. and L.R.W.) independently applied the scoring criteria, and disagreements were resolved through consensus with a third reviewer.

Assessment of Methodological Quality

The methodological quality of the included *in-vitro* studies was evaluated with the QUIN tool. Although the QUIN tool was originally created for dental *in-vitro* studies, it was chosen here because, to our

knowledge, no validated risk-of-bias instrument exists for ophthalmic cell-culture research. Several of its assessment domains—sample selection, randomisation, blinding, outcome reporting, and statistical analysis—are broadly applicable to laboratory-based experimental studies. For each study, twelve criteria were rated “Yes” (2 points), “Partial” (1 point), or “No” (0 points), yielding a maximum score of 24. For the sampling method, a score of 0 was assigned when the procedure was not reported, 1 when partially described, and 2 when fully described (including cell source, passage number, and handling). For randomisation, all studies received a score of 0, since none explicitly mentioned random allocation of dishes or wells, despite this being technically possible in cell culture. Overall percentage scores were calculated as $(\text{Total Score} \div 24) \times 100$. Based on these percentages, studies were classified as having low (>70%), medium (50–70%), or high (<50%) risk of bias⁶. Detailed domain-level scores for all included studies are presented in Appendix 1 (Supplementary Material). The evaluations were carried out independently by two authors (I.K. and L.R.W.), and discrepancies were resolved through discussion, with a third reviewer (H.S.) acting as arbiter when required.

RESULT

Included Studies

The study selection process was conducted in accordance with the PRISMA 2020 flowchart (Figure 1). Database searching yielded 287 records: PubMed (n = 202), ScienceDirect (n = 85), SpringerLink (n = 0), Taylor & Francis (n = 2), and SAGE Journals (n = 3). After removal of 139 duplicates and 3 conference abstracts, 145 records remained. Title and abstract screening eliminated 128 records. During full-text assessment, 3 articles were excluded because their samples originated from injured capsular tissue, and 3 were excluded because the cells had received additional treatments before TGF- β_2 exposure. Detailed reasons for exclusion are provided in Supplementary **Table S1**. Ultimately, 16 studies met the inclusion criteria and were incorporated into the review (Table 2).

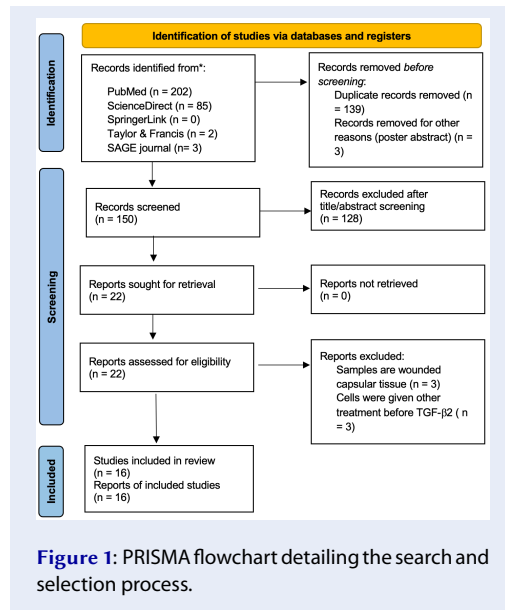

Baseline Characteristic of Included Studies

The selected studies were further analyzed by extracting key information related to PCO modelling, as presented in Table 1. Sixteen studies met the inclusion criteria; four employed lens epithelial cells (LECs) from the SRA01/04 cell line, whereas others utilised primary human lens epithelial (HLE)

cells. Marked variation was observed in the culture media: nine investigations utilised Dulbecco's modified Eagle's medium (DMEM), whereas the remainder adopted modified formulations. With respect to transforming growth factor- β_2 (TGF- β_2), three studies applied 5 ng/mL to induce epithelial-to-mesenchymal transition (EMT), seven applied 10 ng/mL, and the others used alternative concentrations. Eight studies incubated cells for 24 h post-TGF- β_2 exposure; the remainder reported 24–48 h, 2–4 days, or did not specify the duration. Most studies verified TGF- β_2 efficacy by quantitative reverse-transcription polymerase chain reaction (qRT-PCR) and Western blotting. Expression of α -smooth-muscle actin (α -SMA), fibronectin (FN), collagen I (Col I), vimentin and E-cadherin served as canonical fibrotic markers. Collectively, the literature demonstrates that *in-vitro* PCO models can be established by culturing lens epithelial cells in defined media supplemented with TGF- β_2 2,3,7,8. A concentration of 10 ng/mL TGF- β_2 7–13 consistently provoked morphological conversion from cobblestone to elongated, spindle-shaped phenotypes and elicited cataract-like molecular changes 3,12,14, which were confirmed by qRT-PCR and Western blotting. TGF- β_2 exposure up-regulated α -SMA, FN, Col I, vimentin and N-cadherin while down-regulating zonula occludens-1 (ZO-1) and E-cadherin 2,3,7,8,11–13,15–18. NEAT1 expression was likewise elevated; however, no significant difference was observed between 5 and 10 ng/mL 19. Transwell assays further showed that TGF- β_2 enhanced SRA01/04 cell viability, EdU incorporation, invasion and migratory distance 17. Across studies, EMT markers (α -SMA, FN, Col I, vimentin, N-cadherin) were consistently up-regulated, whereas epithelial markers (E-cadherin, ZO-1) were suppressed. Despite methodological heterogeneity (Western blotting, qRT-PCR, immunofluorescence, Transwell assays), most experiments reported pronounced EMT (++/+++), underscoring the robustness of TGF- β_2 -induced fibrotic remodelling in these PCO models.

Risk of Bias Assessment

The methodological quality of the 16 included studies was assessed using the QUIN tool, which evaluates 12 domains, including sample selection, randomisation, blinding, outcome measurement, and statistical analysis; each domain is assigned 0–2 points. All investigations were therefore classified as having a low risk of bias. This uniform rating likely reflects the standardised reporting typically

observed in in-vitro lens epithelial cell experiments, where core procedures are largely harmonised. Conversely, the clustering of scores also highlights a limitation of the QUIN tool, namely its reduced ability to discriminate between methodological strengths and weaknesses when studies follow similar laboratory workflows. The individual QUIN scoring sheets for each of the 12 domains per study are available in **Appendix 1 (Supplementary Material)** for transparency.

Table 2 summarises the characteristics of the 16 included studies. The initial section describes investigations employing established human lens epithelial cell lines (e.g., SRA01/04, HLE-B3, FHL124), whereas the final three studies utilised primary lens epithelial cells or capsular explants. The table lists the culture medium, concentration of TGF-β2, incubation period, EMT-associated markers that were up-regulated, epithelial markers that were down-regulated, and the overall strength of the EMT response.

To visualize heterogeneity in EMT induction, we constructed a heat-map-style table (Figure 2) summarizing cell type, TGF-β2 dose, incubation time, and EMT outcome strength across the included studies. Each row represents a study, whereas the columns employ categorical color-coding to facilitate rapid visual comparison between models. TGF-β2 doses were classified into three categories: low (0–5 ng/mL) shown in yellow, medium (5–10 ng/mL) shown in orange, and high (15–20 ng/mL) shown in

dark orange. Incubation time was similarly categorized as short (≤ 24 h) in light turquoise, intermediate (24–48 h) in mid-blue, and long (> 48 h) in dark blue. EMT strength was depicted using a purple gradient, with weak (+) coded as dark violet, moderate (++) as lavender, and strong (+++) as pink.

This visual synopsis highlights the consistent induction of strong EMT responses (+++) across most studies, particularly at medium to high TGF-β2 doses and incubation periods exceeding 24 h. A minority of investigations employing lower doses or alternative culture systems (e.g., FHL124 cells) exhibited moderate rather than strong EMT outcomes.

DISCUSSION

Preventing posterior capsule opacification (PCO) after cataract surgery is critically important, as it remains one of the most prevalent complications, affecting approximately 50% of patients within five years postoperatively and significantly impairing visual outcomes⁷. Approximately 30% of adults and 100% of children experience vision impairment due to PCO. PCO primarily results from the proliferation and migration of residual lens epithelial cells (LECs), leading to obstruction of the visual axis and often necessitating additional procedures, such as Nd:YAG laser capsulotomy¹. The persistent occurrence of this complication highlights the urgent need for effective strategies to reduce its incidence⁸. Narrative reviews by Nibourg et al. (2015)⁴ and Konopińska et al. (2021)¹ have comprehensively described PCO mechanisms and prevention strategies but have not offered direct comparisons of the experimental conditions used in vitro. The present review analyzes 16 studies that explore variations in culture media, TGF-β2 dosing, and incubation times, which may explain the conflicting results observed among different researchers.

Effective Dose of TGF- β2 that Induced PCO

The available studies consistently demonstrate that TGF-β2 is a potent inducer of epithelial–mesenchymal transition (EMT) in lens epithelial cells (LECs); three studies administered 5 ng/mL, whereas seven used 10 ng/mL. Importantly, a concentration of 10 ng/mL TGF-β2 induces marked morphological changes in LECs, shifting them from a single-layer, cobblestone-like morphology to elongated, spindle-shaped cells characteristic of the fibrotic remodeling that underlies posterior capsule opacification (PCO)⁹. Huang et al. (2020) further

showed that 10 ng/mL TGF- β 2 in Dulbecco's modified Eagle's medium (DMEM) increased SRA01/04 cell migration by approximately 2.5-fold through the miR-497-5p/circ-GGA3 axis. However, the cellular response is time-dependent; 24 h of exposure is sufficient to trigger transcriptional changes, whereas 48–72 h is required for observable phenotypic effects (e.g., stress-fiber formation)¹².

The methodologies used to evaluate the impact of TGF- β 2 comprised quantitative reverse-transcription PCR (qRT-PCR) and Western blot analyses, which confirmed the up-regulation of key epithelial–mesenchymal transition (EMT) and fibrotic markers, including α -SMA, fibronectin (FN), collagen type I (Col I), vimentin and N-cadherin, together with a concomitant down-regulation of E-cadherin^{9, 25}. These markers are critical to validating the fibrotic cataract model because they mirror the conversion of lens epithelial cells (LECs) into a myfibroblastic phenotype, a hallmark of posterior capsular opacification (PCO)²⁶. Notably, NEAT1 expression was also elevated in TGF- β 2-treated cells, implicating this long non-coding RNA in facilitating EMT. NEAT1 participates in diverse cellular processes—including proliferation, migration and differentiation—all of which are pertinent to the fibrotic changes observed in PCO¹⁴. Beyond morphological and molecular alterations, functional read-outs such as Transwell assays demonstrated that TGF- β 2 treatment increased the viability and migratory capacity of SRA01/04 cells, thereby further supporting its role in driving EMT and PCO²³. The crosstalk of multiple signalling cascades, particularly the TGF- β /Smad and Notch pathways, has been implicated in these events, underscoring the complexity of EMT regulation in LECs³. Collectively, these findings highlight the pivotal role of TGF- β 2 in initiating EMT and promoting the development of PCO.

The Preferred Medium

Most studies utilize Dulbecco's Modified Eagle Medium (DMEM) or Minimum Essential Medium (MEM) as the basal medium²⁷. DMEM is preferred because its high glucose concentration (4.5 g L⁻¹), along with abundant amino acids and vitamins, supports robust cell proliferation³⁰. Xie et al. (2022) and Zhang et al. (2018) cultured SRA01/04 cells in DMEM supplemented with 10 % fetal bovine serum (FBS), achieving stable growth and reproducible responses to TGF- β 2 stimulation^{3, 10}. Conversely, serum-free formulations have been adopted

to minimise the influence of endogenous growth factors; for example, Fan et al. (2024) employed such media during ferroptosis assays¹⁷. Although these findings are noteworthy, they remain preliminary and were therefore excluded from the core model-optimisation synthesis.

Fetal bovine serum (FBS) concentrations typically range from 1 % to 20 %, contingent on the experimental objective. Lower concentrations (1–5 %) preserve the slowly proliferating central-lens epithelial phenotype, whereas higher concentrations (10–20 %) approximate the proliferative zone of the lens. Wang et al. (2021) reported that supplementation with 10 % FBS in DMEM/F-12 optimally maintained HLE-B3 viability, although TGF- β 2 concentrations exceeding 10 ng/mL were cytotoxic²⁴. In contrast, serum-free protocols (e.g., Fan et al.) enable the investigation of isolated signaling pathways without interference from serum-derived growth factors¹⁷. The choice of medium depends on the research objective. For proliferation and viability studies, a basal medium consisting of DMEM supplemented with 10 % FBS is commonly used^{28, 29}. To enhance proliferation, epidermal growth factor (EGF, 10 ng/mL) or basic fibroblast growth factor (bFGF, 5 ng/mL) may be added²⁹. Additionally, an extracellular matrix (ECM) component such as gelatin or type IV collagen is frequently included to promote optimal cell adhesion²⁸. In contrast, for EMT and fibrosis induction, a low-serum medium (DMEM + 1 % FBS) is generally preferred to minimize serum interference³⁰. TGF- β 2 (10 ng/mL) is routinely applied for 24–48 h to induce EMT and fibrosis³¹, whereas lapatinib (1 μ M) can be employed to inhibit ErbB signalling, if required³².

Duration of TGF- β 2 Intervention that Induced PCO

Incubation times following TGF- β 2 treatment have been reported to range from 24 h to several days, with eight studies specifically employing a 24-h period. This interval is commonly selected because it permits the initial induction of EMT while limiting prolonged exposure that could elicit additional, potentially confounding, alterations in cellular behaviour³³. Standardizing these parameters ensures that the observed effects can be attributed to TGF- β 2 per se, rather than to secondary changes induced by extended exposure^{9, 32}.

Epithelial identity begins to deteriorate; the mRNA levels of E-cadherin and ZO-1 decrease by 50–70 % within 6–12 h, weakening intercellular junctions and loosening their tight architecture³¹. Concomitantly, fibrotic features emerge, with α -SMA

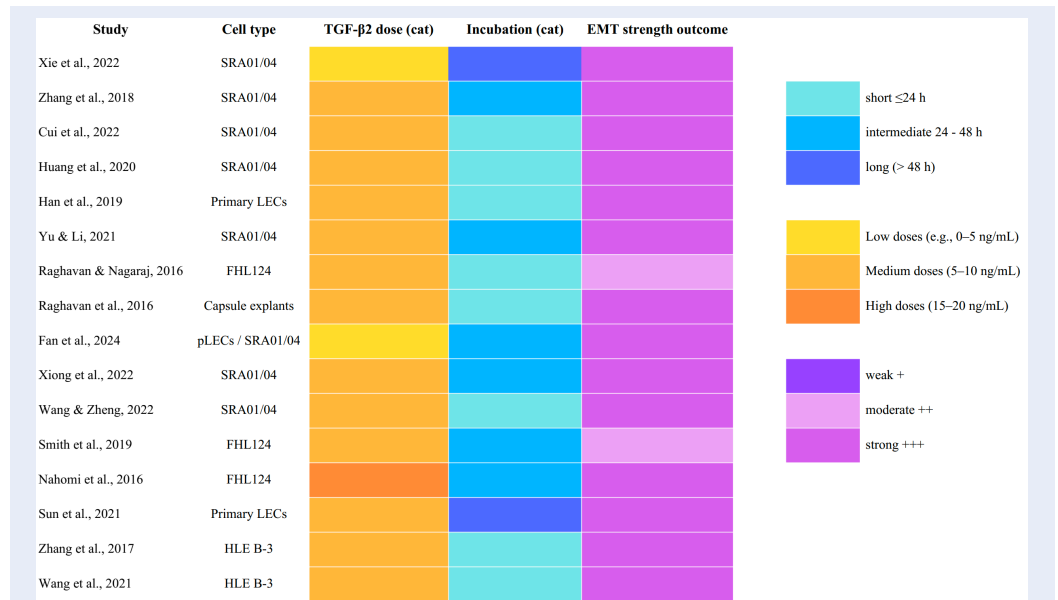

Figure 2: Heat-map synthesis of methodological characteristics and EMT outcomes across 16 included *in-vitro* PCO studies.

and fibronectin expression increasing 2–4-fold by 12–24 h, driven by Smad2/3 phosphorylation and ERK/MAPK activation¹⁶. This transition also triggers autophagy, evidenced by LC3-II accumulation and p62 degradation, which marks a shift in cellular metabolism³³. Supporting these observations, Huang *et al.* (2020) demonstrated that exposure of SRA01/04 cells to TGF-β2 (10 ng/mL) for 24 h produced a 3.5-fold increase in α -SMA protein and a 70 % rise in cell migration, even though the cells had not yet undergone complete morphologic transformation¹². These findings suggest that autophagy may function as a regulatory mechanism alongside EMT, although its role appears to be secondary to the optimization of culture conditions.

This review was conceived to highlight the practical considerations involved in establishing robust *in vitro* posterior capsular opacification (PCO) models. Although epithelial-to-mesenchymal transition (EMT) constitutes the biological foundation of these systems, experimental reproducibility is primarily governed by the technical parameters of the culture milieu. Three variables are particularly influential. First, TGF-β2 concentration: lower concentrations (0–5 ng/mL) induce EMT progressively and preserve cellular viability, whereas higher concentrations (≥ 10 ng/mL) provoke a rapid, fibrotic-like phenotype. Second, incubation duration: a 24 h exposure is most frequently employed and is generally sufficient to up-regulate canonical EMT markers; nevertheless, several studies have extended *in-*

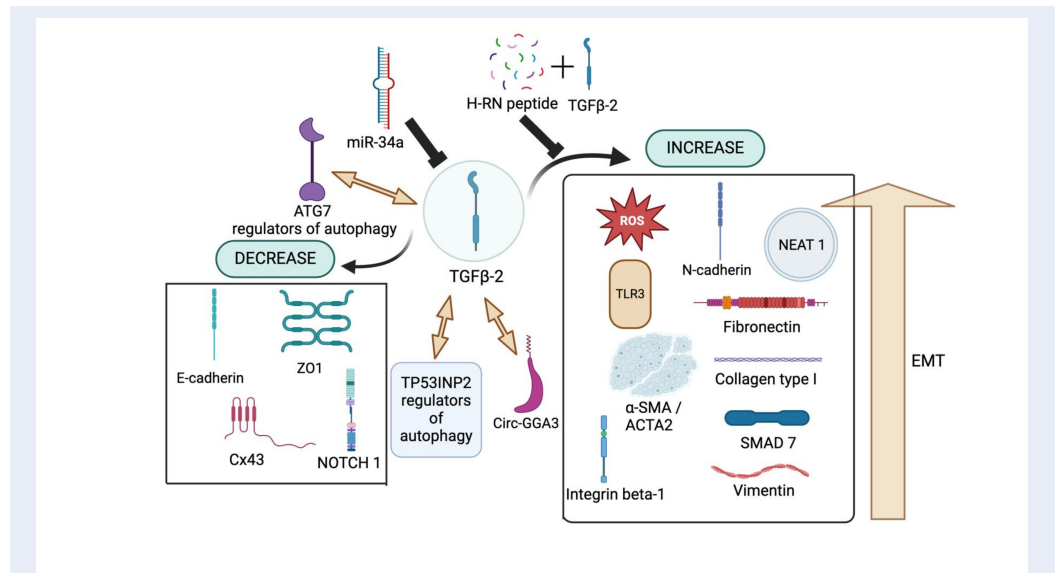

Figure 3: TGF-β2 Regulation on Other Proteins and RNAs. TGF-β2 upregulates or relies on circ-GGA3 to drive cellular changes associated with PCO development. Additionally, TP53INP2 and ATG7 play a crucial role in autophagy while also promoting the EMT process, further contributing to disease progression. On the other hand, H-RN peptide, when combined with TGF-β2, has been shown to inhibit EMT progression, thereby mitigating TGF-β2-driven fibrosis and EMT-related pathologies. Several studies have reported that TGF-β2 upregulates reactive oxygen species (ROS), N-cadherin (N-cad), NEAT-1, TLR3, α-SMA (ACTA2), integrin β-1, collagen type I, vimentin, and the SMAD signaling pathway, all of which are involved in the proliferation and migration of lens epithelial cells (LECs). Conversely, TGF-β2 downregulates key epithelial markers such as E-cadherin (E-cad), ZO-1, connexin 43 (Cx43), and NOTCH1, further facilitating EMT and fibrotic progression.

incubation to 48–96 h to capture more persistent responses or to evaluate therapeutic interventions. Third, the cellular source and substratum: primary human lens epithelial cells seeded on native capsule explants recapitulate the *in vivo* environment more faithfully than immortalised cell lines cultured on plastic. Collectively, meticulous optimisation of dose, timing and culture architecture enhances the fidelity of *in vitro* PCO models and facilitates inter-laboratory comparability. Unlike previous narrative reviews that considered PCO models within broader biological or clinical frameworks, the present review systematically defines the critical experimental parameters and offers actionable guidance for laboratories aiming to optimise and standardise *in vitro* PCO assays.

Several limitations should be acknowledged. The included studies exhibited substantial variability in cell models, culture conditions, TGF-β2 dosing, incubation times, and EMT markers, which limited comparability and precluded quantitative analysis. The vote-counting and semi-quantitative scoring approaches remain subjective, as differences in reporting detail and assay methods may affect how EMT strength is classified. Although the QUIN tool

provides a structured framework, it was not designed for ophthalmic *in-vitro* research and may not fully capture relevant sources of bias, potentially contributing to the clustering of studies in the “low-risk” category. In addition, the review included only English-language full-text articles, which may have introduced language bias and excluded potentially relevant studies. Nevertheless, the review provides a coherent synthesis of TGF-β2-induced EMT models and highlights consistent patterns that may guide future experimental work.

CONCLUSION

The choice of culture medium for lens epithelial cells (LECs) should be guided by specific experimental objectives, the particular cell line, and its responsiveness to growth factors. Based on current evidence, our review indicates that Dulbecco’s modified Eagle’s medium (DMEM) supplemented with 10 % fetal bovine serum (FBS) and 10 ng/mL transforming growth factor-β2 (TGF-β2) for 24–48 hours is the most consistently effective regimen for inducing epithelial–mesenchymal transition (EMT) in LECs, and therefore represents a practical *in vitro* recom-

mendation for future posterior capsular opacification (PCO) investigations.
